Abstract

Recently, there have been a few research efforts towards extending the capabilities of fieldbus networks to encompass wireless support. In previous works we have proposed a hybrid wired/wireless PROFIBUS network solution where the interconnection between the heterogeneous communication media was accomplished through bridge-like interconnecting devices. The resulting networking architecture embraced a Multiple Logical Ring (MLR) approach, thus with multiple independent tokens, to which a specific bridging protocol extension, the Inter-Domain Protocol (IDP), was proposed. The IDP offers compatibility with standard PROFIBUS, and includes mechanisms to support inter-cell mobility of wireless nodes. In this paper we advance that work by proposing a worst-case response timing analysis of the IDP.

1. Introduction

There has been an enormous eagerness towards extending the capabilities of fieldbus networks to encompass wireless support. The RFieldbus European project [2] was just one example of that effort, where PROFIBUS was extended to support hybrid wired/wireless communication systems. In RFieldbus, repeaters were used to provide interoperability between wired and wireless network components (network domains). In any case, in the RFieldbus approach there is only one Single Logical Ring (SLR), with only one token rotating between all the masters (wired or wireless) in the network. The main advantage of such SLR approach is that the effort for protocol extensions is not significant, since the adaptation is essentially at the physical layer level.

However, there are a number of advantages in using a Multiple Logical Ring (MLR) approach to support such type of hybrid systems. This concept was introduced and discussed in [3], and further detailed in [4-5], where a bridge-based approach (thus, layer 2 interoperability) was outlined.

Other works had also suggested the extension of the PROFIBUS standard to support wireless communications. In [13, 16], the authors propose an approach which uses a gateway between the wired PROFIBUS network and the wireless 802.11 network. This gateway acts as a proxy, periodically polling the wireless nodes and retrieving responses to wired nodes, whenever requested by them. A similar approach was proposed in [14], but the wireless communication is supported by PROFIBUS over the 802.11 MAC.

In the MLR approach, each logical ring is comprised of stations that communicate via a unique medium – a domain. Therefore, a wired domain corresponds to the set of (wired) stations that intercommunicates via a wired segment. Correspondingly, a wireless domain is a set of (wireless) stations intercommunicating via the air. In [4-5] we described the functionalities provided by the Inter-Domain Protocol (IDP), which supports the communication between stations in different domains. In those previous works, the mechanisms and functionalities that allow the mobility of station between different wireless cells are also described. These protocol extensions can be supported with mostly no impact to the original PROFIBUS protocol, and thus those extensions provide compatibility with legacy PROFIBUS technologies.

In this paper, we will specifically tackle the problem of the timing analysis of the proposed inter-domain transactions supported the bridge-associated IDP. This work builds on previous relevant works on PROFIBUS real-time assessment [8-12], that have proved the capabilities of this protocol to support distributed computer-controlled systems with stringent real-time requirements. Obviously, the wireless extensions and the bridge-based architecture of our hybrid MLR approach require the development of a new timing analysis, which accounts for the IDP and the effects of the mobility procedure. In this particular paper we will propose solutions, albeit, and essentially because of space limitations, without considering the influence of the inter-cell mobility protocols [4] on the Worst-Case Response Time (WCRT) of the various types of message transactions. Timing analysis considering inter-cell mobility of stations is addressed in a separate work [17].
The reminder of this paper is organised as follows. In Section 2, the main concepts related to bridge-based hybrid wired/wireless PROFIBUS architecture, and particularly to the IDP, are briefly presented. Then, in Section 3, we present a worst-case timing analysis of the IDP-related transactions, to which, in Section 4, a numerical is given. Based on the results presented in Section 4, in Section 5 we provide a discussion on ways towards refining the worst-case analytical formulations. The motivation for that discussion concerns in reducing the level of pessimism that typically exists in such type of formulations in the context of distributed systems. Finally, in Section 6, we draw some conclusions.

2. System architecture

The hybrid wired/wireless fieldbus network includes stations with a wireless interface (radio), that are able to interoperate with wired (legacy) stations. Communication between the different stations is supported by the original PROFIBUS protocol, albeit with specific extensions to support wireless communications and mobility.

In this Section we describe the main characteristics of the PROFIBUS protocol and the previously MLR hybrid wired/wireless architecture.

2.1. Basics of the PROFIBUS protocol

The PROFIBUS Medium Access Control (MAC) protocol uses a token passing procedure [7] to grant bus access to masters, and a master-slave procedure used by masters to communicate with slaves. A PROFIBUS master is capable of dispatching transactions during its token holding time \( T_{TH} \), which, for each token visit, is the value corresponding to the difference, if positive, between the target token rotation time \( T_{TR} \) parameter and the real token rotation time \( T_{AR} \). For further details, the reader is referred to [9].

A master station that sends an Action Frame (the first frame transmitted in a transaction) is said to be the initiator of the transaction, whereas the addressed one (a master or a slave) is the responder. Therefore, a transaction (or message cycle) consists of the request frame from the initiator and of the associated acknowledgement or response frame from the responder. The acknowledgement (or the response) must arrive, to the initiator, before the expiration of the Slot Time \( T_{SL} \), otherwise the initiator repeats the request a number of times defined by the max retry limit, a DLL parameter.

In order to maintain the logical ring, PROFIBUS provides a decentralised ring maintenance mechanism. Each PROFIBUS master maintains two tables – the Gap List (GAPL) and the List of Active Stations (LAS), and may optionally maintain a Live List (LL).

The Gap List consists of the address range from TS (‘This Station’ address) until NS (‘Next Station’ address, i.e., the next master in the logical ring). Each master station in the logical ring starts checking the addresses in its GAPL every time its Gap Update Timer \( T_{GUD} \), a station parameter expires. This mechanism allows masters to track changes in the logical ring, such as addition (joining) or removal (leaving) of stations. This is accomplished by examining (at most) one Gap address per token visit, using the FDL_Request_Status (FDL stands for Fieldbus Data Link Layer) frame.

The LAS is a list of all the masters in the logical ring, and the LL contains all active stations (both masters and slaves).

2.2. Basics on system components

The wireless part of the fieldbus network is supposed to include at least one radio cell. Basically, a radio cell can be described as a 3D-space where all associated wireless stations are able to communicate with each other. In the example of Figure 1, the following set of wired PROFIBUS master (M) and slave (S) stations is considered: M7, M10, S22, S24, S25, S26 and S27. Additionally, the following set of wireless stations is considered: M6, M1, S21 and S23. Within this last set, only M6 and S23 are mobile stations. Three bridge devices are considered: B1, B2 and B3. Each bridge includes two modified PROFIBUS masters implementing the required protocol extensions. We denote each master as Bridge Masters (BM).

![Figure 1. Wireless PROFIBUS example network](image_url)

We are also assuming that the network has a tree-like topology, and that bridges perform routing based on MAC addresses.

In such a system, all wireless communications are relayed through base stations: BS1 and BS2. We will assume, in the remainder of the paper, that M2 and M5 include the base station functionalities in their wireless front-end [1], thus, structuring wireless domains 1 and 2, respectively.

Network operation is based on the Domain-Driven Multiple Logical Ring (MLR) approach, described in [3]. Therefore, each wired/wireless domain has its own logical ring. In this example, four different logical rings
exist: \{(M1 \rightarrow M2 \rightarrow M6), (M3 \rightarrow M4 \rightarrow M7), (M5 \rightarrow M8)\text{ and } (M9 \rightarrow M10)\}.

2.3. Basics on the Inter-Domain Protocol (IDP)

As previously said, in PROFIBUS, a transaction (message cycle) is composed by a request and the related response. The interval between these two actions must be smaller than the value set for the slot time parameter \(T_{sd}\). The use of intermediate bridges demands refining further this message cycle concept (for inter-domain message transaction), since, unavoidably, the inter-domain response will not arrive immediately after the request.

An Inter-Domain Transaction (IDT) is a transaction that involves an initiator and a responder belonging to different domains, i.e. with one or more bridges in the communication path. An IDT is composed of a request (Inter-Domain Request), and its respective response (Inter-Domain Response). We denote the first bridge master in the path from the initiator to a responder as \(BM_i\) (i standing for initiator). Similarly, the last bridge master in the IDT path is denoted as \(BM_r\) (r standing for responder).

The IDP demands that when an initiator makes an Inter-Domain Request, only one of the BMs belonging to the initiator domain – \(BM_i\), codes the frame using the IDP, and relays it. The remaining stations, in the initiator domain, discard the frame.

Then, this frame – the Inter-Domain Frame (IDF) is relayed by the bridges until reaching bridge master \(BM_r\). This bridge decodes the original request frame and transmits it to the responder, which can be a standard PROFIBUS station (for example a PROFIBUS-DP slave). The response is again coded using the IDP and routed back until reaching bridge master \(BM_r\), where it will be decoded and stored.

As the actual response to the original request takes more time than if the responder belonged to the same domain as the initiator, the initiator must periodically repeat the same request until receiving the related response. This means, in practice, that the request is not immediately responded. After \(BM_i\) having received (and stored) the correspondent response frame, then it is ready to respond to the next “retry” request from the initiator. One of the objectives of this mechanism is to provide complete transparency from the point of view of both the initiator and the responder (to cope with PROFIBUS compatibility requirements). This is achieved by \(BM_i\) emulating the responder in a way that the initiator station considers the responder station as belonging to its domain, and by \(BM_r\) emulating the initiator in a way that the responder considers the initiator as belonging to its domain.

Considering the network scenario illustrated in Figure 1, Figure 2 illustrates a simplified timeline regarding a transaction between master M3 and slave S23.

![Figure 2. Example for an Inter-Domain Transaction (IDT)](image_url)

Regarding Figure 2 and the operation of the IDP, we assume that slaves read their inputs periodically, placing their image in the Data Link Layer (DLL) using the PROFIBUS Service \text{\textit{upd}}.req primitive. The image of the input values is placed in a buffer, which is used by the DLL to build a response to a specific request. An indication is returned to the higher layers every time a slave receives a request. This behaviour is implemented by the PROFIBUS-DP protocol. On the initiator side, it is also necessary that the user of the DLL periodically repeats the same request. For every request, the DLL returns a confirmation, which can include “no data” if the response data is not available yet or the addressed slave response in the case that the \(BM_i\) has already received and decoded the IDF carrying the remote response.

2.4. Mobility mechanisms

The inter-cell mobility procedure proposed in [4] is hierarchically managed. One master in the system implements the global mobility management functionality, which is responsible for periodically starting the handoff procedure and controlling some of its phases – the Global Mobility Manager (GMM). In each domain, one master controls the mobility of stations belonging to that domain – the Domain Mobility Manager (DMM). Finally, the bridge stations implement specific mobility services.

The mobility procedure evolves through several phases for which details are provided in [4]. Notably, the mobility procedure can have a significant impact on the worst-case response time of IDTs, and even for transactions between nodes in the same domain. However, and because of space limitations, in this particular paper we will be addressing the timing analysis not considering mobile nodes, and thus not considering the case of systems implementing the inter-cell mobility mechanisms. For this particular setting results are provided in [17].
3. WCRT analysis for IDT transactions

In this Section we start by describing the related work on PROFIBUS timing analysis. Then, we present the proposed analysis for the IDP. Two types of Inter-Domain Transactions (IDT) are addressed:

- when a transaction involves a request and a response – PROFIBUS Send Data with Reply (SDR) and Send Data with Acknowledge (SDA) services;
- and when a transaction only involves a request – PROFIBUS Send Data with No acknowledge (SDN) service.

For further details the reader is referred to [18].

3.1. Related work

The first work which addressed the schedulability of a PROFIBUS network [11], provided just a sufficient schedulability test without presenting any estimation of the worst-case response time for PROFIBUS message streams. In [8] the authors improve that work by suggesting two different approaches to guarantee the real-time behaviour of the synchronous traffic in a PROFIBUS network, and propose a methodology for the calculation of the worst-case response time (WCRT) for a PROFIBUS message transaction. Nevertheless, that methodology can lead to a bit pessimistic results, and thus, in [12], the authors present a even more refined approach. Both approaches proposed in [8] and in [12] will be used as a basis for the timing analysis of our MLR PROFIBUS networks.

The Unconstrained Low-Priority Traffic Profile, one of the analyzable traffic profiles proposed in [8], will be described next, since it is a well known and accepted methodology for the calculation of the WCRT of a PROFIBUS message stream.

With this approach, the real-time requirements for the synchronous (high priority) PROFIBUS traffic are satisfied, even when only one synchronous message is transmitted per token visit, and independently of the asynchronous (low priority) PROFIBUS traffic load. In this way, it is possible to have a guaranteed real-time approach for the message streams, provided that the relative deadline for the synchronous message streams is larger than the related worst-case message response time, which can be computed as follows:

\[ Rslr_i^k = Q^i + Ch^i = nh^k \times T_{cycle}^i + Ch_{cycle}^i \]  

(1)

where \( Q^i \) is the queuing delay, \( nh^k \) is the number of synchronous high-priority message streams generated in master \( k \), \( T_{cycle}^i \) is the worst-case token rotation time and \( Ch^i \) is the worst-case duration of a synchronous message cycle \( i \) issued by master \( k \).

The exact characterisation of the token cycle time properties of PROFIBUS is described in [9], which permits the evaluation the \( T_{cycle}^i \) parameter. An upper bound on the token cycle time can be given by:

\[ T_{cycle}^i = T_{TR} + T_{del}^i = T_{TR} + n \times C_o \]  

(2)

where \( T_{TR} \) is the PROFIBUS target token rotation time, \( n \) is the number of masters, and \( C_o \) is the duration of the longest message cycle in the network. The evaluation of maximum token lateness \( T_{del}^i \) can be more precise and less pessimistic if the duration of the longest message cycles relative to a master is considered. In [9] the authors specifically address this aspect.

3.2. WCRT analysis of IDTs based on SDA or SDR services

The analysis presented in this Section is related to the SDA and SDR PROFIBUS services, in the following Section the SDN service is analysed.

One of the characteristics of the IDP is that the initiator periodically repeats a request until receiving a response. Consequently, the WCRT for a message stream in such conditions mainly depends on the stream period. Figure 3, depicts a scenario where that situation is obvious. In that scenario the response time for the represented message stream, is equal to: \( 2 \times T_{cycle}^i + Rreq_i^k \).

![Figure 3. IDT timing example](image-url)

Consider that \( A_i^k \) is the maximum number of attempts performed by the initiator (master \( k \)) until receiving a valid response from bridge \( BM_i \) related to stream \( i \). \( T_{req}^i \) is the period of a message stream \( i \) from master \( k \). Therefore, the last request, the one that obtains the actual valid response from bridge \( BM_i \) related to stream \( i \), requires a WCRT of \( Rslr_i^k \), which can be calculated using the worst-case response time analysis presented in Section 3.1. That corresponds to the Single Logical Ring (SLR) case.

Then, the WCRT for a stream \( i \) from master \( k \), on a MLR network (\( Rmlr_i^k \)), can be computed using the following formulation:
that initiates the IDT, arrives at
obtains the response arrives at
response ( minimum amount of time, between the first request and
worst-case ( Ci ). In this situation Rslri  
where nh is the number of high priority message streams processed by a BM x. T' cycle is the token cycle time in network domain d. (Creq)'  
To obtain Rbmi it is necessary to account for all the delays experienced by the IDT on the BMs, which depends on the number of streams processed by them and on the traffic conditions on the respective domains.

Thus, using the WCRT analysis for a SLR PROFIBUS network, the following equation allows the calculation of Rbmi for the example outlined, (between M7 and S24):

\[ Rbmi_i = \sum_{j=1}^{b} (nh_f) \times T_{\text{cycle}} + (C_{\text{req}})_{f+1} + b \times \phi + nh_f \times T_{\text{cycle}} + (C_{\text{req}})' + \phi + nh_f \times T_{\text{cycle}} + (C_{\text{resp}})' \]

In this equation, (C_{\text{req}})' , (C_{\text{req}})', (C_{\text{resp}})' , are the time needed to transmit the request, the response and for completing a message cycle on network domain d, respectively.

It is also possible to rewrite equation (5), in a more compact format, as follows:

\[ Rbmi_i = \sum_{j=2}^{\infty} Rslr_{j} + 2 \times b \times \phi \]

where Rslr_{j} is the response time on a single logical ring for a bridge master bm, which can be calculated by any of the SLR WCRT analysis proposed for PROFIBUS.

It is important to note that the IDP defines different frame formats for the frames exchanged between bridges [5], and this aspect must be taken into account when calculating transaction latencies on each domain, as also
the different frame format formats used by the wired and wireless physical layers.

3.3. WCRT analysis of IDTs based on the SDN service

In PROFIBUS the SDN service is used to transmit a frame between an initiator to another station (unicast) or to a group of stations (multicast) or to all stations in the network (broadcast). Since this kind of service is unconfirmed, then the IDP just forwards the frame to other domains without modifications.

As in the case of the SDR and SDA services, it is possible to provide a worst-case time bound for IDTs based on the SDN service involving two stations.

The worst-case time required by a request, from a message stream $i$, to go from a master $k$ to another station $w$ ($R_{k\rightarrow w}^{i}$), can be obtained by adapting equation (5) as follows:

$$R_{k\rightarrow w}^{i} = Rslr_k + \sum_{j=1}^{2n} Rslr_j + b\times\phi$$

where the $u$ in $R_{k\rightarrow w}^{i}$ stands for unicast transaction, the first term of the equation represents the latency on master $k$, and the other terms represent the latency associated with the forwarding by the bridges.

Note, however, that if station $k$ is a BM, then equation (7) needs re-formulation. As an example, consider the network depicted in Figure 5, and the following two transactions: a transaction 1 that involves stations M2 and S21 and a transaction 2 that involves stations M3 and S23. For transaction 1, the first leg of the path is between M2 and M3, with a delay equal to $\phi$, thus the first station in the path, which transmits the message through the network, is M3. For transaction 2, the message is transmitted directly into the network segment by M3. This situation is particularly important for the timing analysis of the mobility procedure (not addressed in this paper), since most of the messages related to the mobility procedure are transmitted in unicast or broadcast modes.

4. Numerical results

In this Section we will illustrate how the WCRT timing analysis presented in the previous section can be applied.

For the remainder of this section consider the network depicted in Figure 1, and the related network parameters as listed on Table 1.

</table>

1. W1 meaning wired
2. W2 meaning wireless
This table is based on typical PROFIBUS parameters, and assumes a wireless infrastructure similar to the RF fieldbus case, where the physical layer of the wireless part of the network is based on the 802.11b protocol [1-2]. Therefore, on the wireless part of the network the data rate is 2.0 Mbit/s, and each frame must include a head and a tail for synchronisation purposes [15].

Consider additionally that system masters have the set of high priority message streams as presented in Table 2. To calculate the transmission duration of the requests and responses, the formulations outlined in [15] have been used. We are also assuming that all message streams have a period of 8ms, and that all frames (request or response) have a size of 20 bytes, for the sake of simplification.

5. Working on reducing the pessimism

The results presented above have a certain level of pessimism, which is inherent to considering the simultaneous occurrence of a number of worst-case situations. Although this may be a fate inherent to all guaranteed approaches based on worst-case scenarios, particularly in the case of distributed event-driven systems, it is important to investigate whether there is room for some improvements (in terms of reducing the pessimism level, in the analytical models).

In this Section we elaborate a bit further on this direction.
Eventually, one of the main sources of pessimism resides in the assumption made on considering that in the worst-case only one high priority message can be processed by a master at each token visit. Also, it may not be a negligible source of pessimism the assumption that all message streams relayed by a bridge master will be ready for transmission at the same time.

While fighting against the first would eventually collide with a basilar (from the real-time perspective) approach for handling such type of real-time guarantees in PROFIBUS networks, the latter probably deserves a second thought. In fact, being able to better model the maximum number of message streams that can be simultaneously queued by the BMs, may strongly impact the values for \( R_{\text{bm}} \) (equation (5)).

For the calculation of \( R_{\text{bm}} \), we assumed a worst-case situation at each bridge, in which all message streams relayed by a BM could be queued for transmission just prior to the instant when a frame related to a message stream \( i \) from master \( k \) arrives at the BM. In fact, that assumption can be somehow relaxed. On a dual port bridge, the messages arriving at the bridge are received in sequence by one of the bridge ports, hereafter called the input BM. At the same time, these messages can be transmitted by the other bridge port – the output BM of the bridge. Consequently, in some cases, when a frame from message stream \( i \) from master \( k \) is queued on the output BM, the output queue will not, simultaneously, have frames from all message streams.

Figure 6 will support further intuition on this. The illustrated example assumes the network structure presented in Figure 1, and describes the sequence of events for transactions between masters M1, M6 and slaves S22, S27 and S25, related to message streams \( S_{1.1} \), \( S_{1.3} \), \( S_{6.1} \) and \( S_{6.3} \), which are represented in Figure 6 by S1.1, S1.3, S6.1 and S6.3, respectively. We are also assuming that no other traffic exists in the network. For convenience, messages transmitted by S22, S27 and S25 are depicted in the same line of BM M3.

![Figure 6. IDTs frames arriving at a BM](image)

In this example, we are considering that all request messages are queued just prior to the reception of the token by M1. As it can be observed, when a frame from message stream \( S_{1.3} \) is ready for transmission by BM M3, the response frame related to message streams \( S_{1.3} \) and \( S_{6.3} \) had already been obtained by bridge B1. In the figure, the queuing delay for \( S_{1.3} \) in master M6 (\( Q_{\text{M6,1}} \)) is shown, as also the queuing delay in BM M3 (\( Q_{\text{M3,1}} \)). \( Q_{\text{M3,1}} \) depends on the number of frames queued on M3 (in this case, 2 considering one from \( S_{1.3} \)), at the arrival of a frame from message stream \( S_{1.3} \) and the ongoing transactions on wired domain 1.

What we add here for computing the worst-case response time, is that it should not be needed to consider that, in all cases, all message streams relayed by BMs are on their output queues simultaneously.

Therefore, we could introduce \( n_{\text{IDT}, \text{bm}} \) as meaning the maximum number of IDT transactions simultaneously queued by a bridge master \( \text{bm} \) (note the impact of \( nh \) in equation (5)).

The analysis presented in Section 3 guarantees that at least one high priority message is dispatched per token visit, thus it is guaranteed that the output queue of a BM is reduced by one element at least once every token visit. We are now trying to devise a general formulation to this problem. Consider a bridge constituted by a bridge master \( k \) and a bridge master \( l \). Bridge master \( k \) receives the incoming traffic from its domain – the input domain, and bridge master \( l \) forwards the traffic to another domain – the output domain.

The incoming traffic can be characterised as follows:

- all message streams related to IDT that use BM \( k \) arrive in sequence;
- we assume that all messages have the same size (\( Cin \)), equal to the minimum size of the input message streams;
- all messages arrive at BM \( k \) with minimal separation.

The traffic forwarded by BM \( l \) can be characterised as follows:

- just prior to receiving the first message concerning input traffic, there is a transmission opportunity;
- the remaining transmitting opportunities are separated by the cycle time of the output domain (\( Cout \)).

Figure 7, depicts, on a simplified time-line, the arrivals at BM M4 and the transmissions by BM M7, which illustrates the assumptions.

![Figure 7. Worst-case relaying scenario](image)

The initial delay, \( D \) is equal to \( Cin + \phi \). To obtain the number of messages which can be transmitted by the output BM, we propose the following algorithm.
Cal_nh'_idt(Cin, nh_idt, tcycle, φ) {
    // F: vector that contains if an IDT has been forwarded by the output BM
    // Analysis interval
    ttotal = Cin × nh_idt;
    D = Cin + φ;
    // initial time
    t = D + tcycle;
    nm = 0
    while t + Cin < ttotal {
        // messeges available
        msg_av = floor(t / Cin);
        if t > nm × Cin and F(nm) == 0 and nm ≤ msg av then
            { F(nm) = 1;
              nm = nm + 1;
            }
        t = t + tcycle;
    }
    nh'_idt = nh_idt – nm
    return(nh'_idt)
}

Figure 8. Algorithm for obtaining nh'_IDT

Consider again the scenario depicted in Figure 1 and the conditions described in Section 4. Figure 9, plots the reduction in the number of message streams (i.e. nhIDT - nh'_IDT) for computing Rbmi, for some of the system BM as a function of the total number of message streams relayed by the BMs: M3, M5 and M9.

6. Conclusions

Recently, there have been a few research efforts towards extending the capabilities of fieldbus networks to encompass wireless support. In previous works [3-5] we have proposed a hybrid wired/wireless PROFIBUS network solution where the interconnection between the heterogeneous communication media was accomplished through bridge-like interconnecting devices. The resulting networking architecture embraced a Multiple Logical Ring (MLR) approach, thus with multiple independent tokens, to which a specific bridging protocol extension, the Inter-Domain Protocol (IDP), was proposed. The IDP offers compatibility with standard PROFIBUS and supports inter-cell mobility of wireless nodes. In this paper we advance that work by proposing a worst-case response timing analysis of the IDP.

This type of analysis has typically a certain level of pessimism, which is inherent to the consideration a simultaneous occurrence of a number of worst-case situations. Although this is the fate of guaranteed approaches based on worst-case scenarios, particularly for distributed event-driven systems, in the last section of this paper we also introduced some ways to improve further the proposed analytical formulations.

Ongoing work is now being carried out concerning incorporating the timing behaviour of the inter-cell mobility protocol already defined for the architecture, to which preliminary findings are already available in [17].
